Surface Modification of Magnesium Ferrite Nanoparticles for Selective and Sustainable Remediation of Congo Red

Supawitch Hoijang, Tanapong Kunakham, Jeeranan Nonkumwong, Kajornsak Faungnawakij, Supon Ananta, Piyarat Nimmanpipug, T. Randall Lee, and Laongnuan Srisombat*

ABSTRACT: Surface modification of silica-coated magnesium ferrite nanoparticles (MgFe2O4@SiO2 NPs) by 3-aminopropyltriethoxysilane (APTES) shows enhanced selectivity for the removal of Congo Red (CR) from both single and binary aqueous dye solutions. Before coating the surfaces of amine-functionalized magnesium ferrite nanoparticles (MgFe2O4−NH2 NPs) with silica, control studies of the adsorption of cationic, neutral, and anionic dyes were performed using both single and binary dye systems. The studies found that the MgFe2O4−NH2 nanoadsorbent favors the adsorption of indigo carmine (IC) and CR in single dye solutions (>90% removal efficiencies). However, MgFe 2O4−NH2 NPs preferentially adsorb CR in binary dye solutions. Interestingly, the selectivity of CR over IC depends on the initial concentration of IC/CR in the IC/CR binary systems. A further enhancement in the selective removal of CR in both single and binary dye solutions was achieved by coating the MgFe2O4−NH2 NPs with silica followed by modification with APTES (i.e., APTES-modified MgFe2O4@SiO2 NPs). The highly selective adsorption capacity for CR on the APTES-modified MgFe2O4@SiO2 nanoadsorbent was attributed to the mixture of polar functional groups (i.e., −OH and −NH2) on the surface of the nanoadsorbent, which facilitates adsorbent−adsorbate interactions such as electrostatic and hydrogen-bonding interactions, which are amplified for CR with its more numerous polar functional groups (i.e., amine, azo, and sulfonate groups). From the results, the APTES-modified MgFe2O4@SiO2 nanoadsorbent offers an effective, inexpensive, and reusable/sustainable system for the selective removal and remediation of Congo Red from wastewaters.

1. INTRODUCTION

Water pollution has been an ongoing societal concern due to continuing worldwide industrial growth. Industries involving coloring, such as textile, leather, and printing, are of particular concern as dyes are major pollutants of wastewater. The abundant amounts of dyes in effluents are harmful to both organisms and humans. In addition to their high toxicity and resistance to biodegradation, the dyes are often mutagenic and can cause cancer in humans. To reduce water pollution, it is necessary to remove or recover the contaminated dye in wastewater before returning the water to natural resources. Among various approaches for dye removal, adsorption has received much attention due to its high performance, simplicity of operation, and ready availability of several adsorbents. Numerous studies have explored the use of magnetic nanomaterials, especially ferrite-based nanoparticles, as efficient adsorbents. These materials not only provide the ability to remove various contaminants but also are easily separated from the treated solution after the adsorption process using an external magnet, thereby providing a pathway toward a reusable and sustainable remediation technique. Among ferrite-based nanoparticles, magnesium ferrite suits to use as an alternative adsorbent since it is a superparamagnetic and noncytotoxic material that offers both practical usage and environmental safety.

Selectivity is one of the most important factors when choosing a good adsorbent. An adsorbent with high selectivity for removal of the targeted dyes can be utilized to recover the targeted molecule and/or to serve as a sensor for the detection and identification of certain types of dyes. However, the design of adsorbents with binding abilities to specific molecules

is challenging since there are several factors influencing selectivity. For example, the surface charge of the adsorbent directly affects the selectivity of dye adsorption. Qin et al. reported that quaternary amine-functionalized polymers showed selective removal of anionic dyes. Likewise, Chen and co-workers fabricated secondary amine-functionalized silica for the selective adsorption of anionic dyes. The existence of amine-based functional groups on the surfaces of these adsorbents provides positive charges that are suitable for attractive electrostatic interactions with anionic molecules. Therefore, surface modification stands as an attractive strategy to design adsorbents with high selectivity for targeted dye removal.

In recent years, surface-functionalized magnesium ferrite nanoparticles (MgFe$_2$O$_4$ NPs) have been fabricated by our research group. Perhaps the most interesting materials are the amine-functionalized MgFe$_2$O$_4$ NPs (MgFe$_2$O$_4$−NH$_2$) in which ethanolamine is used as a surface modifier. MgFe$_2$O$_4$−NH$_2$ NPs can be utilized as efficient adsorbents for the removal of hazardous substances, such as heavy metal ions like Pb(II) and anionic dyes like Congo Red. High removal efficiencies (>90%) for these contaminants of MgFe$_2$O$_4$−NH$_2$ NPs were obtained. Interestingly, with regard to selectivity, MgFe$_2$O$_4$−NH$_2$ NPs provided high selectivity for Pb(II) adsorption in binary solutions containing Pb(II) and various metal ions such as Ca(II), Cd(II), Zn(II), Cu(II), and Ni(II) ions. With regard to dye removal, except for CR adsorption, the adsorption behavior of MgFe$_2$O$_4$−NH$_2$ NPs toward other dyes has not been examined. As such, the specificity of dye removal by these nanoadsorbents has yet to be determined.

In this study, the adsorption behaviors of several dyes by MgFe$_2$O$_4$−NH$_2$ NPs were systematically investigated. Different types of dyes (i.e., cationic, neutral, and anionic dyes) were used as model contaminants in single-component systems to evaluate the ability to adsorb each type of dye under various initial pH values of a dye solution. In addition to single-component dye solutions, the adsorption behaviors of dyes in binary solutions with either different (e.g., cationic vs anionic) or similar (e.g., anionic vs anionic) types of dyes were also examined with the goal toward selective adsorption of CR. However, when examining the removal of anionic dyes, the MgFe$_2$O$_4$−NH$_2$ NPs provided efficient adsorption of both CR and anionic indigo Carmine (IC) even in binary IC/CR mixtures, indicating that the MgFe$_2$O$_4$−NH$_2$ NPs lack high selectivity for CR removal. To address this shortcoming, we encapsulated the MgFe$_2$O$_4$−NH$_2$ NPs within a thin silica shell followed by amino functionalization (3-aminopropyltriethoxysilane, APTES) on the silica surface to increase the selectivity for CR. APTES was used as a surface modifier since not only it provides structural stability and inertness to redox reactions of the magnetic nanoadsorbent but also provides an amine group on the surfaces of the modified adsorbents, which offers the linking of a specific adsorbate. Several characterization techniques (i.e., X-ray diffraction (XRD), Fourier transform infrared (FTIR) spectroscopy, X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM), and ζ-potential analysis) were employed to characterize the modified nanoadsorbent. The adsorption behavior of anionic dyes, in particular IC and CR, in both single and binary systems was examined using the as-modified nanoparticles.

### 2. EXPERIMENTAL SECTION

#### 2.1. Materials

The amine-functionalized magnesium ferrite nanoparticles (MgFe$_2$O$_4$−NH$_2$ NPs) were synthesized by following our previous work, wherein details of the preparation method and characterization are fully provided. The synthesis of MgFe$_2$O$_4$−NH$_2$ NPs is given in the Supporting Information.
samples of the representative dyes Congo Red (CR, Loba Chemie), indigo carmine (IC, Merck), methyl orange (MO, KemAUS), methylene blue (MB, Merck), rhodamine B (RhB, Loba Chemie), and neutral red (NR, Sigma-Aldrich) were used as model contaminants. The chemical structures and the maximum absorption wavelength ($\lambda_{\text{max}}$) of these dyes are listed in Table 1. Absolute ethanol (C$_2$H$_5$OH, Labscan), 25–28% ammonia solution (NH$_4$OH, Merck), and 3-aminopropyltriethoxysilane (APTES, Sigma-Aldrich) were used in the surface-modification process.

### 2.2. Selective Adsorption of Dyes by MgFe$_2$O$_4$–NH$_2$ NPs

#### 2.2.1. Selectivity Test for Dye Removal in Single-Component Dye Systems

To explore the selectivity of the MgFe$_2$O$_4$–NH$_2$ nanoadsorbent, single and binary systems of dyes were used as model contaminants. The single-component systems were composed of 10 mg L$^{-1}$ individual dyes: IC, CR, MO, NR, MB, and RhB. Various initial pH values of the dye solutions (i.e., 3–11) were studied in these systems by adjusting the pH of the solution using 0.1 mol L$^{-1}$ nitric acid and 0.1 mol L$^{-1}$ sodium hydroxide. Batch adsorption experiments were performed in triplicate. In the studies, 15 mL of dye solution was mixed with 2.8 g L$^{-1}$ MgFe$_2$O$_4$–NH$_2$ NPs and then shaken using a shaking water bath (Membrex, WB22/SV1422) at $\sim$30 °C for 4 h. Afterward, the nanoadsorbent was separated from the dye solution by an external magnet. Absorption spectra of the solutions were collected using a UV–vis spectrophotometer (PG Instruments, T80) to determine the amount of dye in the solution for calculating the removal efficiency and adsorption capacity ($q_e$) using eqs 1 and 2, respectively.

\[
\text{removal efficiency (\%)} = \frac{[(C_0 - C_f)/C_0]}{100}
\]

\[
q_e (\text{mg g}^{-1}) = \frac{(C_0 - C_f)/W}{V}
\]

where $C_0$ and $C_f$ are the dye concentration at initial and equilibrium states (mg L$^{-1}$) and $V$ and $W$ are the volume of the dye solution (L) and dry weight of the nanoadsorbent (g), respectively. For the single-component dye systems, $C_0$ and $C_f$ of each dye were estimated using a standard calibration curve.

#### 2.2.2. Selectivity Test for Dye Removal in Binary Dye Systems

The binary systems were composed of three sets of two mixed dyes: anionic/cationic (IC/RhB and CR/RhB), anionic/neural (IC/NR), and anionic/anionic (IC/CR), MO/CR, and IC/CR). The batch adsorption experiments were performed similar to those described in Section 2.2.1, except the mixed solution contained 10 mg L$^{-1}$ each dye component and the initial pH value of all mixed dye solution was $\sim$7. For the binary system, the removal efficiency and $q_e$ were calculated using eqs 1 and 2, respectively. The $C_0$ and $C_f$ of each dye in the mixture were determined using the linear equations in two variables applied from Beer’s law for a multicomponent system$^{20}$ as expressed in eqs 3 and 4.

\[
\text{at } \lambda_1: \quad A_1 = \varepsilon_{X1}^\lambda b C_X + \varepsilon_{Y1}^\lambda b C_Y
\]

\[
\text{at } \lambda_2: \quad A_2 = \varepsilon_{X2}^\lambda b C_X + \varepsilon_{Y2}^\lambda b C_Y
\]

where $A_1$ and $A_2$ are the total absorbances of the mixtures at wavelengths 1 and 2 with respect to $\lambda_{\text{max}}$ of dyes X and Y, respectively; $\varepsilon_{X1}^\lambda$, $\varepsilon_{X2}^\lambda$, $\varepsilon_{Y1}^\lambda$, and $\varepsilon_{Y2}^\lambda$ are the values of extinction coefficient for dyes X and Y at wavelengths 1 and 2, respectively; $C_X$ and $C_Y$ are the concentrations of dyes X and Y in the binary solutions, respectively; and b is the length of the beam in absorbing media (i.e., width of the cuvette).

#### 2.2.2. Competitive Adsorption between Congo Red and Indigo Carmine in Binary Systems on MgFe$_2$O$_4$–NH$_2$ NPs

Two sets of IC/CR binary solutions were used. One set of solutions had a 1:1 ratio of the IC/CR concentration (i.e., 10:10, 50:50, 100:100, 150:150, and 200:200 mg L$^{-1}$). The second set had varied ratios of the IC/CR concentration as 1:1, 1:2, 1:3, 1:4, 2:1, 2:1, and 1:1 (i.e., 50:50, 50:100, 50:150, 50:200, 150:50, and 100:50 mg L$^{-1}$, respectively). The procedure for adsorption experiments was similar to that described in Section 2.2.2.

### 2.3. Enhanced Selective Removal of Congo Red by APTES-Modified MgFe$_2$O$_4$@SiO$_2$ NPs

#### 2.3.1. MgFe$_2$O$_4$–NH$_2$ NPs Coated with Silica and Modified with APTES

This process was conducted via two steps as follows: (i) surface coating by silica to prepare the silica-coated MgFe$_2$O$_4$–NH$_2$ NPs (MgFe$_2$O$_4$@SiO$_2$ NPs) and (ii) surface functionalization to obtain the amine-functionalized MgFe$_2$O$_4$@SiO$_2$ NPs (APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs). The MgFe$_2$O$_4$@SiO$_2$ NPs were prepared following the well-known Stöber method, as previously reported in our work.$^{21}$ The amine-functionalization method was slightly modified from Kim et al.,$^{22}$ as illustrated in Scheme 1. Briefly, 200 mg of the as-obtained MgFe$_2$O$_4$@SiO$_2$ powder was mixed with 100 mL of absolute ethanol and 6 mL of ammonia solution. Afterward, 1.07 mmol of APTES was rapidly injected into the mixture, stirred for 8 h, and then refluxed at 90 °C for 1 h. The precipitate was separated from the mixture using an external magnet and washed with ethanol several times. The final product was then dried in an open-air oven at 60 °C overnight.
2.3.2. Characterization. The phase formation of the as-synthesized APTES-modified MgFe2O4@SiO2 NPs was monitored by X-ray diffraction (XRD, Rigaku SmartLab) using Cu Kα radiation (λ = 1.5406 Å) with 0.02° scan steps at 2θ ranging from 10 to 90°. The functionalization of these nanoparticles was identified by attenuated total reflectance–Fourier transform infrared spectroscopy (ATR–FTIR, Thermo Scientific Nicolet iS50) by varying wavenumbers from 400 to 4000 cm⁻¹ with a resolution of 4 cm⁻¹. Their morphologies were explored by field emission scanning electron microscopy (FE-SEM, Kratos AXIS Ultra DLD) having a monochromatic Al Kα X-ray source of 14866 eV. The C 1s peak at 285.0 eV was used as an internal standard reference. The ζ-potential curve was detected at room temperature using a Zetasizer Nano ZS (Brookhaven ZetaPALS) by adjusting the pH of the solution from 3 to 12 using 0.1 mol L⁻¹ hydrochloric acid and 0.1 mol L⁻¹ sodium hydroxide. The powders were carefully dispersed using 0.1 mg mL⁻¹ concentrations and then adjusting the ionic strength to 1 × 10⁻3 mol L⁻¹ using sodium chloride.

2.3.3. Selectivity Test for Anionic Dye Removal in Single and Binary Systems. To demonstrate the selective removal capacity for anionic dyes of the as-synthesized APTES-modified MgFe2O4@SiO2 NPs, the removal of IC and CR dyes in both single-component and binary systems (IC/CR) was performed by employing the procedure described in Section 2.2.2. However, in this current section, the initial pH and concentration of the dye solutions were kept constant as ~6 and 30 mg L⁻¹, respectively.

2.3.4. Reusability Test for CR Removal by APTES-Modified MgFe2O4@SiO2 NPs. To examine the reusability of the nano-adsorbent, adsorption–desorption studies were performed. In the first cycle of the adsorption process, 2.8 g L⁻¹ fresh APTES-modified MgFe2O4@SiO2 NPs was added to 15 mL of 30 mg L⁻¹ CR solution and then shaken at ~30 °C for 4 h. Afterward, the nano-adsorbent was separated from the solution using an external magnet. Absorption spectra of the solutions were collected using a UV–vis spectrophotometer to calculate the removal efficiency for CR. The CR-adsorbed nano-adsorbent was dried in an open-air oven at 60 °C overnight. Then, the first cycle of the desorption process was performed by adding the dried nano-adsorbent to 15 mL of absolute ethanol at pH ~12 (i.e., adjusted by 0.1 mol L⁻¹ sodium hydroxide) for release of the adsorbed CR dye from the nano-adsorbent. After the desorption process, the nano-adsorbent was separated, washed with deionized water, and then dried at 60 °C for 6 h for further use in the second adsorption process. In the current study, five adsorption–desorption cycles were conducted for each assay.

3. RESULTS AND DISCUSSION

3.1. Selective Removal of Dyes by MgFe2O4–NH2 NPs. 3.1.1. Effect of Initial Solution pH on Selective Adsorption in Single-Component Dye Systems. Three types of representative dyes, i.e., anionic (IC, CR, and MO), cationic (MB and RhB), and neutral (NR) dyes, were used as adsorbates; their molecular structures and ionization states at pH 7 are shown in Table 1. The adsorption behaviors of these dyes by MgFe2O4–NH2 NPs at the initial pH of dye solution ranging from ~3 to ~11 are demonstrated in terms of the removal efficiency, as shown in Figure 1. The colors of the solutions and UV–vis spectra for each dye before and after the adsorption processes are provided in Figure S1. Generally, the influence of solution pH on the adsorption system can be rationalized by the adsorbent and adsorbate interactions. The charges in the adsorbent surface significantly depend on the solution pH. A net zero charge appears on the adsorbent surface when the solution pH is equal to the pH at the point of zero charge (pH_{PZC}), estimated from the ζ-potential curve. When pH < pH_{PZC}, the surface is positively charged and becomes negative at pH > pH_{PZC}. In this study, the pH_{PZC} of the MgFe2O4–NH2 NPs is ~8.4. The behavior of the dye contaminant can be influenced by several factors such as charges, the number of binding sites, and so on. In the set of cationic dyes, low removal efficiencies for MB (~8%) and RhB (2%) are obtained at pH values ranging from ~3 to ~7 (see Figure 1). Within this pH range, the MgFe2O4–NH2 surface exists as positively charged (pH < 8.4), which leads to strong electrostatic repulsion between the positively charged surface of the adsorbent and the positive charges on the MB and RhB molecules (see the structures in Table 1). Even though the charge on the adsorbent surface can plausibly become negative at pH > 8.4, the removal efficiencies for MB and RhB are still quite low. On the whole, the results indicate that the MgFe2O4–NH2 NPs are ineffective for the removal of cationic dyes.

We employed neutral red (NR) as a representative of neutral dyes. However, since NR is a pH indicator, it can exist in two chemical forms (see Figure S2a). Depending on the solution pH, the cationic (NRH⁺, pH < 6.8) and neutral (NR, pH > 8.0) forms exhibit red and yellow colors, respectively. The removal efficiencies for NR at pH ~3 and ~5 are not reported in this study due to the blue shift in the absorption band during the adsorption processes (see Figure S1c). The removal efficiencies slightly increased from ~11 to ~18% with increasing pH from ~7 to ~11, respectively (see Figure 1). At pH ~7, the dye molecules are likely composed of both NRH⁺ and NR forms, whereas the NR form is only present at pH ~11. These observations can be rationalized as follows. First, the repulsion between the positively charged surface of the nano-adsorbent (pH < 8.4) and the NRH⁺ form likely occurs at pH ~7. Second, the NR form could be adsorbed via other interactions (e.g., hydrogen bonding) rather than electrostatic interactions. Although the removal efficiencies for NR of the MgFe2O4–NH2 NPs are slightly higher than those observed for MB and RhB, low removal efficiencies were still obtained. We therefore conclude that the MgFe2O4–NH2 NPs are not effective for the removal of NR—a conclusion similar to that obtained for the cationic MB and RhB dyes.

High removal efficiencies (>90%) were observed for the anionic IC and CR dyes at pH values ranging from ~3 to ~11 (see Figure 1). Moreover, no significant changes of the removal efficiencies for IC and CR were revealed, indicating that the adsorption of these dyes was pH-independent. Previously, Regti et al. reported a similar phenomenon involving the pH-independent adsorption of Basic Yellow 28.
dye by activated carbon. Greater than 90% dye removal efficiencies were obtained at pH values ranging from 2 to 12. In our previous report, we investigated the influence of initial solution pH on CR adsorption by MgFe2O4−NH2 NPs. The results found that the CR removal efficiencies were strongly influenced by the initial pH of the CR solution. With an increase of pH from ∼2 to ∼6, the CR removal efficiencies increased from ∼80 to ∼96% and then remarkably decreased to lower than 50% at pH ∼12. The main adsorption mechanism was then proposed to occur via strong electrostatic attraction between the negative charges of the −SO3− groups on the CR molecules and the positively charged surface of the adsorbent. In addition to electrostatic interaction, dipole−dipole hydrogen-bonding (between the electronegative amine group of the dye and O atom/surface −OH groups of the adsorbent) and Yoshida hydrogen-bonding (between the aromatic ring on the dye molecule and the −OH group on the adsorbent surface) interactions could also be involved in the adsorption mechanisms. Compared to our previous report, the only different adsorption parameter is the initial concentration of the dye: in the present study, we used 10 mg L−1 dye compared to 30 mg L−1 in the previous study. It is possible that the lower initial concentration of dye could perhaps influence the adsorption mechanism. Moreover, Liu et al. reported that electrostatic interactions were not the predominant factor controlling pH-independent adsorption phenomena. Therefore, we believe that, in this study, other adsorbent−adsorbate interactions (e.g., dipole−dipole hydrogen-bonding and Yoshida hydrogen-bonding interactions) likely play an important role in the adsorption of IC and CR on MgFe2O4−NH2 NPs due to the slight change of removal efficiencies at all values of the solution pH. Interestingly, this comparison points out that, apart from the effect of initial pH, the initial dye concentration might also be an important factor that influences the adsorption mechanism.

For MO adsorption (see Figure 1), the removal efficiencies noticeably decreased from ∼44 to ∼23% after tuning the pH from ∼5 to ∼11. However, the removal efficiency at pH ∼3 is not reported because the protonated form of MO (see Figure S2b) gives rise to a blue shift in the MO absorption band during the adsorption process, as illustrated in Figure S1f. The decrease in MO removal efficiencies as a function of pH can perhaps be attributed to an increase in the negative charge on the adsorbent surface, leading to charge−charge repulsion between the adsorbent and MO molecules at elevated pH values. Interestingly, although MO is an anionic dye similar to IC and CR, a quite low removal efficiency for MO (<50%) was observed. Our result is in agreement with previous studies. Even though MO is the smallest molecule studied, it provides lower removal efficiency. Based on the chemical structures shown in Table 1, MO possesses only one −SO3− group, while IC and CR possess two −SO3− groups. IC and CR contain a greater negative charge than MO, leading to stronger binding to the positively charged MgFe2O4−NH2 nanoadsorbent surface.

Additionally, hydrogen bonding plays an important role in IC and CR removal since IC and CR contain primary and secondary amines that offer greater opportunity to form hydrogen bonding with the nano-adsorbent. Consequently, the MgFe2O4−NH2 nano-adsorbent efficiently removes anionic dyes, particularly IC and

Figure 2. (Top) Digital photos and (bottom) UV−vis spectra of anionic/cationic (a) IC/RhB and (b) CR/RhB and (c) anionic/neutral IC/NR binary dye solutions before and after adsorption by MgFe2O4−NH2 NPs. (d) Relative removal efficiencies of dyes in anionic/cationic and anionic/neutral binary dye solutions at pH ∼7.
CR, in single-component dye systems. Furthermore, the highest removal efficiencies for these dyes are obtained at pH \(\sim 7\); we therefore used this pH in all further studies.

### 3.1.2. Selectivity of MgFe\(_2\)O\(_4\)−NH\(_2\) NPs in Binary Dye Systems.

To confirm the inefficient removals of cationic and neutral dyes, the adsorption studies in cationic/cationic (MB/RhB) and cationic/neutral (MB/NR and RhB/NR) binary solutions were investigated. The results indicate unfavored adsorption of cationic and neutral dyes, as shown in Figure S3.

To demonstrate the selective removal of anionic dyes by MgFe\(_2\)O\(_4\)−NH\(_2\) NPs in binary dye solutions, three sets of the solutions, (1) anionic/cationic (IC/RhB and CR/RhB), (2) anionic/neutral (IC/NR), and (3) anionic/anionic (IC/MO, CR/MO, and IC/CR), were used as adsorbates. As illustrated in Figure 2a, the color of the IC/RhB solution changed from purple to fuchsia, which is similar to the color of RhB, after the adsorption process. Correspondingly, the absorption band of IC decreased, while that of RhB remained unchanged. These observations indicate that the MgFe\(_2\)O\(_4\)−NH\(_2\) NPs preferentially remove IC (removal efficiency \(\sim 95\%\)) in the presence of RhB (removal efficiency \(\sim 6\%\)) in IC/RhB mixtures. Similarly, the color of the CR/RhB solution changed to fuchsia after the adsorption process (see Figure 2b). Correspondingly, the absorption band of CR significantly decreased, while that of RhB remained unchanged. These observations indicate the preferential removal of CR (\(\sim 100\%\) removal efficiency) over RhB (\(\sim 0\%\) removal efficiency) by the MgFe\(_2\)O\(_4\)−NH\(_2\) NPs in the CR/RhB solution. In the set of the anionic/neutral binary solution, the color of the IC/NR mixture faded from purple to light yellow (see Figure 2c). The absorption band for CR was not detectable, whereas the NR band decreased after the adsorption process. Interestingly, the NR removal efficiency in IC/NR binary solutions (\(\sim 22\%\)) was higher than that of the single-component NR solution (\(\sim 11\%\), see Figure 1). However, the increase in the NR uptake does not affect the IC adsorption efficiency (\(\sim 98\%\)) in IC/NR binary solutions. Therefore, the adsorption behaviors of anionic/cationic and anionic/neutral binary solutions by the MgFe\(_2\)O\(_4\)−NH\(_2\) nanoadsorbent show that the nanoadsorbent exhibits highly selective removal of the anionic dyes IC and CR.

To provide additional evidence for the selective removal of anionic dyes by MgFe\(_2\)O\(_4\)−NH\(_2\) NPs, the adsorption behaviors of anionic/anionic binary solutions were examined. The results are provided in Figure 3. The color of the IC/MO mixed solution changed from green to yellow after exposure to the nanoadsorbent (see Figure 3a). The absorption band of IC disappeared, while that of MO substantially decreased. Likewise, the color of the CR/MO solution turned yellow, and the overlapping UV−vis absorption band of CR/MO became similar to the characteristic band of MO after the adsorption process (see Figure 3b). The removal efficiencies for IC (\(\sim 95\%\)) and CR (\(\sim 98\%\)) in the MO-based binary solutions are high (see Figure 3d) and similar to those in the single-component systems (see Figure 1). Higher removal efficiencies for IC and CR than that for MO are due to stronger electrostatic \(^{25,29,31}\) and hydrogen-bonding \(^{28,31,35}\) interactions, as mentioned in Section 3.1.1.

In Figure 3c, the color of IC/CR solution changed from dark purple to colorless after the adsorption process, which is consistent with undetectable IC and CR absorption bands for these experiments. These results demonstrate that IC and CR
dyes were removed by the nanoadsorbent, consistent with the high removal efficiencies for IC (∼97%) and CR (∼97%). However, high removal efficiencies for IC and CR (almost 100%) in the IC/CR binary solution can be attributed, at least in part, to low initial IC/CR concentrations (i.e., 10:10 mg L\(^{-1}\)). A previous study found that a high removal efficiency for CR (∼96%) was obtained using 30 mg L\(^{-1}\) initial CR concentration. \(^{16}\) Similarly, our preliminary studies found an IC removal efficiency of ∼96% using 30 mg L\(^{-1}\) initial IC concentration (data not provided). Therefore, the use of low initial concentrations of IC/CR in binary solutions might be unable to distinguish the adsorption behaviors of IC and CR dyes. With regard to the results in this section, we conclude unable to distinguish the adsorption behaviors of IC and CR. The concentration (data not provided). Therefore, the use of low initial concentrations of IC/CR in binary solutions might be unable to distinguish the adsorption behaviors of IC and CR dyes. With regard to the results in this section, we conclude unable to distinguish the adsorption behaviors of IC and CR.

3.1.3. Competitive Adsorption between Congo Red and Indigo Carmine on MgFe\(_2\)O\(_4\)−NH\(_2\) NPs. Two sets of IC/CR binary solutions were used as adsorbates. The first set was fixed as a 1:1 ratio of IC/CR concentrations such as 50:50, 100:100, 150:150, and 200:200 mg L\(^{-1}\). Figure 4a shows that the 50:50 mg L\(^{-1}\) IC/CR solution turned blue after the adsorption process. Similarly, when the initial IC/CR concentration was expressed as follows

\[ K_D = \frac{q_e}{C_e} \]  

where \(q_e\) and \(C_e\) are the amount of adsorbed dye on the adsorbent (mg g\(^{-1}\)) and the amount of dye remaining in solution (mg L\(^{-1}\)) at the equilibrium state, respectively. The ratio of two distribution coefficients (i.e., \(K_{D,IC}\) and \(K_{D,CR}\)) can be used to rationalize the selectivity of dye X in the X/Y binary solution expressed as follows

\[ \alpha_{X/Y} = \frac{K_{D,X}}{K_{D,Y}} \]

Importantly, a value of \(\alpha\) close to 1.0 indicates no selectivity by the proposed adsorbent.

Table 2 shows the partition coefficients and selectivity factors for both IC and CR in the IC/CR binary solutions at various initial concentrations, which were kept constant at a 1:1 concentration ratio. The obtained values of \(\alpha_{CR/IC}\) (0.983) are close to 1 for the 10:10 mg L\(^{-1}\) IC/CR concentration, indicating a lack of selective adsorption of IC and CR by the nanoadsorbent. However, at the 50:50 mg L\(^{-1}\) IC/CR concentration, the \(\alpha_{CR/IC}\) value increased to the highest value (5.88), whereas the \(\alpha_{IC/CR}\) value decreased to the lowest value (0.170). These results indicate that the MgFe\(_2\)O\(_4\)−NH\(_2\) nanoadsorbent preferentially removes CR rather than IC at this concentration. With a further increase in the initial IC/CR concentration to 200:200 mg L\(^{-1}\), the \(\alpha_{CR/IC}\) value significantly dropped to 2.18, while the \(\alpha_{IC/CR}\) value slightly increased, leading to a decrease in the selective adsorption of CR by the nanoadsorbent. Interestingly, the molecular selectivity of the MgFe\(_2\)O\(_4\)−NH\(_2\) nanoadsorbent seems to be influenced by the initial dye concentration, which is consistent with the report by Saghian and co-workers. \(^{35}\) In the present study, although the

values of $\alpha_{CR/IC}$ decreased with an increase in the IC/CR concentration (starting at 50:50 mg L$^{-1}$), all obtained values were higher than 1.0 and higher than the $\alpha_{IC/CR}$ values, indicating greater selectivity for CR over IC by the nanoadsorbent.

In the second set of experiments (see Figure 5), the ratios of IC/CR concentrations were varied when divided into two subsets. In the first subset, the initial CR concentration was kept constant at 50 mg L$^{-1}$ and mixed with various concentrations of the IC solution (i.e., 100, 150, and 200 mg L$^{-1}$) to obtain 2:1, 3:1, and 4:1 ratios of IC/CR concentrations, respectively. The complementary procedure was performed in the second subset to obtain 1:2, 1:3, and 1:4 ratios of IC/CR concentrations. The changes in the colors of the solutions during the adsorption studies and the adsorption capacities of IC and CR by the MgFe$_2$O$_4$–NH$_2$ NPs are illustrated in Figure 5. By keeping the CR concentration constant, the adsorption capacities of IC slightly increased with an increase in the initial IC concentration from 50 to 200 mg L$^{-1}$ (see Figure 5b). In contrast to the fixed IC concentration studies, the adsorption capacities of CR significantly increased (see Figure 5b). These results indicate that although the ratios of the IC/CR concentration were varied, the MgFe$_2$O$_4$–NH$_2$ nanoadsorbent preferentially adsorbed CR rather than IC due to the higher adsorption capacity of CR compared to that of IC. Furthermore, the results are in good agreement with the results described in the first set.

In these studies, the molecular selectivity of the MgFe$_2$O$_4$–NH$_2$ nanoadsorbent could be affected by hydrogen-bonding interactions. Based on the chemical structures of CR and IC (Table 1), the $\sim$NH$_2$ groups of CR provide stronger hydrogen-bonding capacity than the $\sim$NH$^-$ group of IC. In addition, CR bears $\sim$N=N$^-$ groups, which can form hydrogen bonds with the surface of the nanoadsorbent. For the studies described in this section, the MgFe$_2$O$_4$–NH$_2$ NPs preferentially adsorbed CR rather than IC. However, the MgFe$_2$O$_4$–NH$_2$ nanoadsorbent was able to remove either IC or CR, indicating a lack of specificity for CR. Therefore, it is necessary to develop a new type of nanoadsorbent for the selective adsorption of Congo Red.

3.2. Enhanced Selective Removal of Congo Red by APTES-Modified MgFe$_2$O$_4$@SiO$_2$ NPs. 3.2.1. Characterization of APTES-Modified MgFe$_2$O$_4$@SiO$_2$ NPs. XRD patterns of the MgFe$_2$O$_4$ NPs after the two-step surface modification by silica and APTES are shown in Figure 6a. All diffraction patterns of the as-synthesized powders are well indexed to JCPDS card no. 88–1935, which is according to the cubic spinel MgFe$_2$O$_4$. The broadening of the diffraction peak at two-theta values ranging from 20 to 30 degree can be attributed to coating with silica. These findings suggest that silica encapsulation and APTES functionalization of MgFe$_2$O$_4$ NPs do not influence the crystal structure of MgFe$_2$O$_4$. In addition, no extra diffraction peaks were found, indicating that the pure phase of MgFe$_2$O$_4$ is maintained after the surface modification processes. FTIR spectra illustrating the functionalization of MgFe$_2$O$_4$ NPs are provided in Figure 6b. After coating with silica, the bands at $\sim$3400 and $\sim$948 cm$^{-1}$ are assigned to the hydroxyl (O$-$H) stretching and bending vibration modes of the silanol (Si$-$OH) group, respectively. In addition, the band at $\sim$3400 cm$^{-1}$ can be attributed to adsorbed water molecules due to the detection of the O$-$H bending vibration of water at $\sim$1630 cm$^{-1}$. The broad and strong band at $\sim$1060 cm$^{-1}$ and the band at $\sim$794 cm$^{-1}$ correspond to the stretching and bending vibration modes of the siloxane (Si$-$O$-$Si) group, respectively. The vibration of metal oxides is also found at $\sim$552 cm$^{-1}$. After surface functionalization by APTES, the characteristic FTIR bands detected in MgFe$_2$O$_4$@SiO$_2$ NPs are also observed, whereas the characteristic bands of APTES (e.g., C$-$H and N$-$H vibrations) are not readily evident. This observation is in agreement with the previous studies. These studies reported that FTIR spectra of APTES-modified nanoparticles did not show the characteristic band of the APTES molecule due to the small amount of APTES species on the surface and/or the overlapping of $\sim$NH$_2$ vibration bands with those of the hydroxyl groups. In addition, Chan and Kazarian mentioned that the sensitivity of the FTIR technique is low for materials with weak absorption or when band overlapping between the minor and major components occurs.

To clarify the nature of the surface functionalization, we used XPS to characterize the MgFe$_2$O$_4$@SiO$_2$ NPs before and after treatment with APTES. The corresponding survey spectra are shown in Figure 6c. All XPS spectra show the existence of
Mg, Fe, O, and Si elements, which is consistent with the chemical composition of MgFe$_2$O$_4$@SiO$_2$ NPs, and these results are in good agreement with the FTIR results. In addition, a signal for N was detected in the spectrum of the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs, which can be attributed to the APTES molecules. Two different chemical environments of N 1s were found in the high-resolution XPS spectrum of the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs (see Figure 6d). The N 1s signals at $\sim 399.6$ and $\sim 401.4$ eV correspond to free amine (−$\text{NH}_2$) and protonated amine (−$\text{NH}_3^+$) groups, respectively.46 These results support the successful surface functionalization of the MgFe$_2$O$_4$@SiO$_2$ NPs by APTES.

Analysis of the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs by SEM (see Figure 6e) reveals spherical nanoparticles with smooth surfaces, similar to the pristine MgFe$_2$O$_4$@SiO$_2$ NPs reported in a previous study.21 The $\zeta$-potential was also measured to explore the surface charge properties of the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs at pH values ranging from $\sim 3$ to $\sim 12$. Estimated from the $\zeta$-potential curve (see Figure 6f), the pH at the point of zero charge (pH$_{pzc}$) of the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs is $\sim 6.1$. The obtained pH$_{pzc}$ value is lower than the pK$_a$ of the propylamine surface group ($\sim 10.6$), which can be attributed to the negatively charged surface of silica.51 However, the existence of APTES moieties on the surfaces leads to an increase in pH$_{pzc}$ for the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs when compared to that for the MgFe$_2$O$_4$@SiO$_2$ NPs ($\sim 4.9$).21 With regard to the characterization results obtained from XRD, FTIR, XPS, SEM, and $\zeta$-potential analysis, we conclude that APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs were successfully obtained in this study.

The magnetism of the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs was examined by monitoring the response of the NPs to an external magnet in efforts to separate the nanoadsorbent from the solution. These studies found that the nanoadsorbent was rapidly separated from the solution within a few minutes (see Figure 7), indicating excellent magnetic response. In addition, the facile separation of the magnetic nanoadsorbent gives a convenient platform for reusability/sustainability.

3.2.2. Selectivity of APTES-Modified MgFe$_2$O$_4$@SiO$_2$ NPs in Single-Component and Binary Dye Systems. The as-synthesized APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs were utilized to investigate the selective removal of CR from both single-component and binary dye solutions. In these studies, the adsorption of dyes was investigated using 30 mg L$^{-1}$ dye solution at pH $\sim 6$. The initial solution pH $\sim 6$ was selected from the $\zeta$-potential curve (Figure 6f). The dye concentration
(30 mg L$^{-1}$) was selected according to the study on the effect of initial concentration of CR solution on CR adsorption, as shown in Figure S4. The removal efficiency for CR shows no significant change with an increase in CR concentration from 10 to 30 mg L$^{-1}$ and then decreases with a further increase in CR concentration. Figure 8a shows the colors of the solutions and UV-vis spectra of the single-component dye solutions before and after the adsorption processes. The color of the IC solution slightly faded with a small decrease in the intensity of the UV–vis absorption band of IC. In contrast, the CR solution changed from red to colorless, and the intensity of the CR absorption band decreased dramatically. The removal efficiencies for IC and CR in the single-component dye solutions were ~6 and ~95%, respectively (see Figure 8a). Interestingly, the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs preferentially adsorb CR rather than IC as demonstrated by the large difference in the removal efficiencies for IC and CR.

To investigate further the highly selective removal of CR by the APTES-modified MgFe$_2$O$_4$@SiO$_2$ nanoadsorbent, we tested binary IC/CR dye systems. In Figure 8b, the color of the IC/CR solution turned blue after the adsorption process. The UV–vis absorption band for IC was largely unchanged, whereas the intensity of the CR band was strongly reduced, corresponding to ~0 and ~94% removal efficiencies for IC and CR, respectively. From the results, we conclude that APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs show enhanced selective removal of CR compared to MgFe$_2$O$_4$–NH$_2$ NPs.

The highly selective adsorption of CR by APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs can be rationalized by the synergistic interplay between the adsorbent and the adsorbate. We believe that the surfaces of APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs comprise the amine (–NH$_2$) and hydroxyl (–OH) groups, which originate from the immobilized-APTES molecules and silica surfaces, respectively. The interaction between the CR molecules and the mixture of functional groups on the nanoadsorbent surfaces can be modulated by the electrostatic

Figure 7. (a) Full-scale and (b) magnified digital photos of the magnetic separation over time of the APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs.

Figure 8. Digital photos and UV–vis spectra of (a) single-component and (b) binary dye solution systems before and after adsorption by APTES-modified MgFe$_2$O$_4$@SiO$_2$ NPs, along with the relative removal efficiencies for the dyes at pH ~6.
attraction between the protonated amine groups of the nanoadsorbent and the polar functional groups of the CR molecules (i.e., amine, azo, and sulfonate groups). Even though the IC molecules also possess sulfonate groups, the adsorption results indicate that the APTES-modified MgFe₂O₄@SiO₂ nanoadsorbent does not preferably adsorb IC. From Table 1, the CR molecules are composed of two of each of the following functional groups: −NH₂, −N−N−, and −SO₃⁻, whereas IC possesses only two −SO₃⁻ groups. Consequently, the enhanced adsorption of CR by the nanoadsorbent is likely driven by two types of interactions as follows: (1) the dipole−dipole hydrogen-bonding (H-bonding) interactions between −NH₂ or −N−N− groups of the CR molecules and the −OH groups of the adsorbent surface and (2) Yoshida H-bonding interactions between the aromatic ring of the CR molecules and the −OH groups of the adsorbent surface.⁵,¹³,¹⁴

In separate studies, we undertook computational simulations to explore the basis for the selective adsorption of CR. The net polarity of the IC and CR molecules, namely, the dipole moment (μ), was approximated from the optimized electronic structure of the molecule, as given in Figure S5 and Table S1. The calculated dipole moment of CR is markedly higher than that of IC, which is consistent with the high chemical reactivity of the CR molecules.⁶ In addition, the atomic charges of N of the CR molecules obtained from natural bond orbitals (NBO) analysis are given in Table S2. The atomic charges of N attributed to free amine groups of CR are more negative than that of pyrrole N of IC. These results thus provide additional support to our hypothesis of enhanced intermolecular interactions leading to stronger dipole−dipole H-bonding interactions between the CR molecules and the adsorbent surface.

3.2.3. Reusability Test for CR Removal by APTES-Modified MgFe₂O₄@SiO₂ NPs. In addition to sufficient selective removal of CR, the reusability of APTES-modified MgFe₂O₄@SiO₂ NPs for CR removal was studied. The adsorption−desorption studies of CR by the nanoadsorbent for five cycles are shown in Figure 9. High removal efficiencies for CR (∼98%) were obtained in the first three cycles, which then decreased to ∼92% in the fourth cycle. After the fifth cycle, the removal efficiency for CR still remained high at ∼86%. Generally, the APTES-modified MgFe₂O₄@SiO₂ nanoadsorbent provides an excellent selective and reusable/sustainable system for CR removal.

4. CONCLUSIONS

Amine-functionalized magnesium ferrite nanoparticles (MgFe₂O₄−NH₂ NPs) synthesized by our research group were used as nanoadsorbents for the adsorption of various types of organic dyes (i.e., cationic, neutral, and anionic dyes). The results demonstrated that the anionic dyes, especially IC (>90%) and CR (>90%), were removed by MgFe₂O₄−NH₂ NPs from single-component and binary mixtures of dye solutions. In addition, studies of the competitive adsorption between IC and CR indicated that the MgFe₂O₄−NH₂ NPs preferentially adsorbed CR (separation factor = 5.88) over IC (separation factor = 0.170) in IC/CR binary solutions. Interestingly, the selective removal of CR by MgFe₂O₄−NH₂ NPs depended on the initial dye concentrations in the IC/CR binary solutions. However, the MgFe₂O₄−NH₂ NPs were able to remove both IC and CR dyes, indicating a low selectivity by the nanoadsorbent. The surface of the MgFe₂O₄−NH₂ NPs was further modified to achieve selective removal of CR. The surface modification was performed using two steps: (1) coating the MgFe₂O₄−NH₂ NPs with silica to afford MgFe₂O₄@SiO₂ NPs; and (2) surface functionalization of the MgFe₂O₄@SiO₂ NPs by 3-aminopropyltriethoxysilane (APTES) to obtain APTES-modified MgFe₂O₄@SiO₂ NPs. Characterization by XRD, FTIR, XPS, SEM, and ζ-potential analysis confirmed the successful synthesis of the APTES-modified MgFe₂O₄@SiO₂ NPs. Adsorption studies showed that the APTES-modified MgFe₂O₄@SiO₂ nanoadsorbent provided highly selective removal of CR rather than IC in both single-component and binary mixtures of dye solutions. The enhanced selective removal of CR by the APTES-modified MgFe₂O₄@SiO₂ NPs was rationalized on the basis of the following: (1) the mixture of polar functional groups (i.e., −OH and −NH₂) on the surface of the nanoadsorbent, (2) the chemical nature of the dye molecules (i.e., molecular charge and functional groups), and (3) synergistic effects of the adsorption mechanism (i.e., electrostatic and hydrogen-bonding interactions). On the whole, the APTES-modified MgFe₂O₄@SiO₂ NPs offer several attractive characteristics (i.e., high performance, excellent selectivity, facile and rapid magnetic separation, and good reusability) for the removal/remediation of CR from polluted waters.
